KEMPER LEARNING DYNAMICS WORKSHOP - 20-MINUTE TALK

When can dendritic structure help local credit assignment?

From backpropagation to neuron coordinates, dendritic addresses, conductance-dependent route gain, and an alignment boundary

Houman Safaai · Maceo Richards · Bernardo L. Sabatini
Kemper Institute, Harvard University · Harvard Medical School

01 / 20

SAY THIS

I will ask when dendritic structure can help a network learn from locally available signals. We will move from backpropagation to local learning and then to dendritic address and gain. The answer is conditional: useful routes require both sufficient feedback bandwidth and task-route alignment.

LIKELY QUESTION

Do dendrites replace backpropagation?

ANSWER

No. Backpropagation is our exact reference. We test when restricted, dendrite-compatible feedback retains enough of that information to support learning.

PURPOSE

State the question and the conditional answer before introducing details.

HOW TO READ IT

The subtitle previews the argument: coordinate, address, route gain, then the alignment boundary.

CLAIM GUARDRAIL

Do not claim a biological implementation of backpropagation.

TRANSITION

First, what information problem does any learning rule have to solve?

02 Learning changes network weights; credit assigns each change

0:50 · scripted

THE PROBLEM Learning changes network weights; credit assigns each change

$$\mathcal{L} = \mathcal{L}(f(x; w), y) \quad \Delta w_i = -\eta \partial \mathcal{L} / \partial w_i$$

• A global objective must be converted into a destination, sign, and magnitude for every trainable weight.

PURPOSE

Define credit assignment in language shared by machine learning and computational neuroscience.

HOW TO READ IT

Follow the forward arrows to the loss, then the highlighted reverse route to one weight. Read the equation as delta w_i equals minus eta times the loss derivative.

CLAIM GUARDRAIL

Keep the distinction between the optimization rule and the mechanism that supplies its derivative.

SAY THIS

A neural network maps an input to an output through many trainable weights. Training begins with one global loss, but the optimizer needs a separate update for every weight. Credit assignment is this conversion: for each parameter, which parameter should change, in which direction, and by how much? The equation at the bottom is ordinary gradient descent. The difficult object is not the forward activity itself; it is the derivative of the global loss with respect to a parameter that may be many stages upstream. This is the common problem that backpropagation and proposed neuronal learning rules must address.

LIKELY QUESTION

Is credit assignment just another name for gradient descent?

ANSWER

Gradient descent specifies how to use a derivative. Credit assignment is the problem of computing or approximating the parameter-specific information that derivative requires.

TRANSITION

Backpropagation tells us exactly what that returned information would be.

THE MATHEMATICAL REFERENCE

Backpropagation defines the exact neuron-specific learning signal

$$Z_u = \sum_i w_{iu} x_i + b_u, \quad y_u = f_u(Z_u)$$

$$\delta u \equiv \partial \mathcal{L} / \partial y_u = \sum_{v \in \text{downstream}} w_{vu} F_v'(Z_v) \delta v$$

δu is exact back information assigned to neuron u —not yet to any weight.

feedforward feedback feedback alignment, direct feedback

internal targets or states equilibrium propagation, predictive coding

eligibility + learning signal three-factor rules, spike

dendritic teaching signals synapse-specific, local approximation models

Backpropagation is the information reference; biological theories differ in how the returned signal is produced.

PURPOSE

Introduce the exact reference and situate the work among alternative credit-assignment approaches.

HOW TO READ IT

The recursion sums over neurons v downstream of u . Delta u belongs to a neuron, not yet to an individual incoming weight.

CLAIM GUARDRAIL

Do not imply that feedback alignment, equilibrium propagation, and three-factor rules are equivalent mechanisms.

SAY THIS

For a point neuron u , the downstream network returns delta u , the derivative of the loss with respect to that neuron's output. The reverse recursion multiplies downstream errors by synaptic weights and activation derivatives, so delta u is specific to the neuron and generally nonlocal. We use this as an information reference, not as a claim that a brain literally runs backpropagation. Existing approaches replace or infer this signal in different ways: fixed feedback, state-based objectives, eligibility traces with modulatory factors, or dendritic teaching signals. Our question is complementary: once feedback is restricted, what spatial coordinates can a neuron and its dendrites provide?

LIKELY QUESTION

Why is delta u not already weight-specific?

ANSWER

All incoming weights of neuron u share the same downstream loss derivative. Their different presynaptic activities and local derivatives make their final gradients distinct.

TRANSITION

That shared structure gives the standard local factorization.

POINT-NEURON LOCAL LEARNING

Local learning preserves eligibility and approximates the returned signal

$$\partial \mathcal{L} / \partial w_i = \underbrace{x_i f'(u(z; u))}_{\text{local eligibility } e_i} \times \underbrace{\delta u}_{\text{exact neuron signal}}$$

$$\Delta w_i = -\eta e_i \delta_{\text{avail}} u$$

one layer-wide scalar m

Every neuron receives the same task-dependent coordinate.

one signal $\delta_{\text{avail}} u$ per neuron

Feedback identifies the postsynaptic neuron while the eligibility remains weight-specific.

A shared scalar does not equalize the weights: each update still contains a different eligibility e_i .

Locality determines where an update is computed; feedback bandwidth determines what task information it can use.

Notes: Fox & Denker (2001), Perreault & Germain (2016).

24 / 28

PURPOSE

Define local learning and pre-empt the misconception that a shared scalar collapses neurons.

HOW TO READ IT

Read the factorization from left to right: local eligibility e_i times exact neuron signal δu ; the available signal replaces only the second factor.

CLAIM GUARDRAIL

Call this a bandwidth bottleneck, not neuronal collapse.

SAY THIS

For a point neuron, the exact weight gradient factorizes into a local eligibility and a neuron-specific loss signal. Eligibility uses quantities available at the connection: presynaptic activity and the postsynaptic derivative. A local rule can preserve this exact factor while replacing δu by whatever learning signal is available. At one extreme every neuron receives the same scalar; at the other, feedback preserves one coordinate per neuron. A shared scalar does not make all weights equal, because every weight still has its own eligibility. It limits the rank of task-dependent learning information, so diversity remains but is underused.

LIKELY QUESTION

Would one shared error make the hidden layer behave like one neuron?

ANSWER

No. Different inputs, activations, initial weights, and eligibilities keep units distinct. The limitation is feedback bandwidth: only one task-dependent direction is broadcast per example.

TRANSITION

A point neuron offers one destination; a dendritic neuron offers many internal destinations.

FROM A POINT TO A TREE

Dendrites turn one neuronal signal into four testable routing questions

network weight $w_i \rightarrow$ synaptic conductance g_i on compartment i

$$\delta V_{ij} = A_{ij} c_j, \quad A_{ij} \in \mathbb{R}^{N \times K}, \quad c_j \in \mathbb{R}^K$$

A_{ij} says where each feedback channel is delivered; c_j contains the K signed values available on the current example.

1. coordinate + ownership

Which neuron, and which arbor, receives each signal?

2. dendritic address

Which compartment in arbor receives it?

3. route gain

How strongly does it reach that destination?

4. task-route alignment

Does the available route span match the credit demanded by the task?

The experiments test coordinate, address, gain, and alignment separately instead of treating "dendrites" as one intervention.

PURPOSE

Define the paper's organizing variables before any dendritic result is shown.

HOW TO READ IT

A_{ij} has one row per compartment and one column per available channel. Multiplying by c_j produces one available value at every compartment.

CLAIM GUARDRAIL

Grouped-point controls can emulate the same routing matrix; an address need not uniquely require dendritic material.

SAY THIS

We now replace one point unit by a neuron with N internal compartments. The available compartment field is A_{ij} times c_j . The matrix A_{ij} specifies where each of K feedback channels is delivered; c_j contains their signed values on the current example. This separates four questions that are often conflated. Coordinate asks whether feedback identifies the correct neuron. Ownership asks whether that coordinate reaches the correct arbor. Address asks which subtree within the arbor receives it. Gain asks how strongly the signal propagates. Finally, alignment asks whether these available routes span the credit pattern the task actually demands.

LIKELY QUESTION

Is A_{ij} the anatomical adjacency matrix?

ANSWER

No. It is a delivery or address matrix. Anatomy can generate its columns, but matched non-anatomical and deranged matrices let us separate route capacity from a specific topology.

TRANSITION

To derive how route gain works, we need the conductance model.

DIRECTED-TREE STEADY STATE
Conductance makes dendritic voltage a normalized quotient

$G^E, G^I, G^A, G^S \geq 0$
 E and I are distinguished by reversal potentials, E^I and E^A may be negative conductance.

$g^{tot}_n = g^L_n + G^E_n + G^I_n + G^{child}_n$, $R^{tot}_n = 1/g^{tot}_n$

$V_n = R^{tot}_n (g^L_n E^L_n + G^E_n E^E_n + G^I_n E^I_n + j^{child}_n)$

additive current
Changes the numerator without changing total conductance.

shunting conductance
Raises g^{tot}_n and lowers R^{tot}_n , even when net shunt current is small.

$V_n \approx E^I_n = g^I_n / (g^I_n + G^S_n) < 0$, but g^I_n still changes the denominator.

$G^S_n \gg G^E_n, G^I_n$
A shunt raises g^{tot}_n and lowers R^{tot}_n without changing the numerator.

● Shunting changes local sensitivity because conductance appears in the voltage denominator.

Watt & Rieke (1987), Chance et al. (2002), Ocker & Sejnowski (2012)

SAY THIS

Each compartment receives nonnegative excitatory and inhibitory conductances. They are not distinguished by positive versus negative weights; they are distinguished by their reversal potentials. At steady state, voltage is the total reversal-weighted current divided by total conductance. Excitation and inhibition therefore affect the numerator, while both also increase the denominator and reduce local input resistance. Our additive control changes current without changing total conductance. A shunt can carry almost no net current when voltage is near the inhibitory reversal potential and still change the denominator. That denominator effect is what can regulate sensitivity and the gain of a credit route.

PURPOSE

Define excitatory, inhibitory, additive, and shunting terms before deriving gradients.

HOW TO READ IT

G^E and G^I are sums of active synaptic conductances. R^{tot} is the reciprocal of leak, synaptic, and effective child conductance.

CLAIM GUARDRAIL

The additive comparison is a current-based control, not a claim that all point-neuron inhibition is additive.

LIKELY QUESTION

How can inhibition matter when its instantaneous current is near zero?

ANSWER

Because conductance changes input resistance. Near the inhibitory reversal potential the numerator contribution can vanish while the denominator still increases.

TRANSITION

Differentiating this steady state reveals what a synapse can compute locally and what must be transported.

EXACT LOCAL FACTOR · TRANSPORTED ERROR

The exact dendritic gradient is local eligibility $\times$ transported compartment error $\delta^n_{comp} \propto \partial \mathcal{L} / \partial V_n$: exact error assigned to compartment n of neuron u

$$\partial \mathcal{L} / \partial g_i = \underbrace{\mathbf{x}_i \mathbf{R}^{loc}_i (E^{rec}_i - V_n)}_{\text{local dendritic eligibility } e^{rec}_i} \times \underbrace{\delta^n_{comp}}_{\text{transported compartment error}}$$

$$\delta^n_{comp} = \delta^n_{comp} \tilde{\alpha}_n$$

$$\tilde{\alpha}_n = \prod_{(i,j) \in \text{path}(n \rightarrow 0)} E^{rec}_i(V_j) R^{rec}_{i,j} \tilde{g}^{rec}_{i,j} \tilde{g}^{rec}_{j,i}$$

Directed tree: one exact path product. Reciprocal cable: the same field is obtained from the steady-state adjoint.

one somatic error δ^n_{comp}

is transported into a full tree compartment

Feedback must deliver a compartment-specific field; the synaptic eligibility itself is local and exact.

Arbore (2007), Pando (2007) Science, Ullrich & Dean (2012)

07 · 18

PURPOSE

Present the central gradient factorization and distinguish directed-tree transport from the general adjoint.

HOW TO READ IT

Read the first equation as local dendritic eligibility times transported compartment error. Alpha tilde n is dimensionless route gain along the directed path.

CLAIM GUARDRAIL

Do not present one directed path as the general Green's function of a reciprocal cable.

SAY THIS

For conductance g_i on compartment n , the exact gradient again has two factors. The local eligibility contains presynaptic activity, local input resistance, and the driving force between the synaptic reversal potential and local voltage. The second factor is δ^n_{comp} : how the loss changes if voltage at that compartment is perturbed. In the directed-tree approximation, this compartment error equals the somatic error times a path gain, $\tilde{\alpha}_n$, which is a product of local derivatives, resistances, and coupling conductances along the unique path to the soma. For reciprocal cable models, the same error field is obtained by solving the steady-state adjoint.

LIKELY QUESTION

Does the path-product formula apply to a fully reciprocal dendrite?

ANSWER

Not literally. It is exact for the directed-tree model. The more general result is the adjoint linear solve; the eligibility-times-compartment-error factorization remains valid.

TRANSITION

We can now abstract any restricted feedback pathway as an operator on this exact field.

THE CREDIT OPERATOR

A feedback pathway selects, assigns, and scales stochastic credit

stochastic BP gradient
 $\mu_{BP} = \mu + \xi$

credit operator M
select assign scale

available local update
 $\mu_{local} = M \mu_{BP}$

$\mu_{BP} = \mu + \xi, \quad E[\xi] = 0, \quad \text{Cov}(\xi) = \Sigma$

$\mu_{local} = M \mu_{BP}, \quad w = \mu_{local} - \eta \text{gradient}$

$M = I$: unrestricted backpropagation of the stochastic gradient. Restricted routes change the span, assignment, or gain of the available update.

The operator M lets one theory describe scalar, neuron-specific, subtree-targeted, and exact compartment feedback.

08 / 18

PURPOSE

Introduce the common mathematical object used to compare feedback schemes.

HOW TO READ IT

M acts on the stochastic gradient field. It can restrict span, reassign coordinates, or rescale them.

CLAIM GUARDRAIL

This is a local linearization of delivered credit, not a claim that every biological pathway is globally linear.

SAY THIS

Let μ plus ξ denote a stochastic exact gradient: μ is its mean task-aligned component and ξ is zero-mean sampling noise. A feedback architecture applies an operator M before the update. Identity M gives unrestricted backpropagation. A scalar broadcast, one coordinate per neuron, subtree routes, deranged routes, and an exact compartment field are different choices of M . This abstraction separates the forward neuron from the information geometry of its learning signal. It also lets us ask one quantitative question across experiments: how much useful signal does a restricted route retain, and how much update energy and noise does it admit?

LIKELY QUESTION

Is M learned by the model?

ANSWER

Not necessarily. The theory describes any fixed or state-dependent delivery operator. In our controlled comparisons, M is prescribed so its effects can be isolated.

TRANSITION

The signal-noise utility follows from the smoothness bound for one update.

SIGNAL-NOISE PHASE THEORY

Operator utility balances retained signal, update cost, and noise

OPERATOR UTILITY · POSITIVE TASK ALIGNMENT REQUIRED

$$U(\mathbf{M}) = \frac{|\mathbf{p}^T \mathbf{M} \mathbf{p}|^2}{2I_{\text{quad}}[\mathbf{M} \mathbf{p}]^2 + \text{tr}(\mathbf{M} \mathbf{E} \mathbf{M}^T)}$$

task-aligned signal route-step update cost admitted stochastic noise

 $\rho_{\text{p}} = 0.937$

utility versus observed norm-matched one-step progress across 540 trained conditions

 $\rho_{\text{a}} = 0.916$

utility versus final trained accuracy

Exact for an isotropic quadratic with Hessian $\mathbf{L}_{\text{quad}}$; otherwise a curvature bound and one-step smoothness guarantee. It predicts large contrasts and when fairly progress—not every trajectory-accrued difference.

Restricted routing helps only when its retained, aligned signal compensates for the signal it discards and the noise it admits.

20 / 28

PURPOSE

Make the phase theory the predictive centerpiece and state its scope honestly.

HOW TO READ IT

Read U of $\mathbf{M}$ as aligned signal squared divided by curvature times routed signal-plus-noise energy.

CLAIM GUARDRAIL

Lead with prediction of large contrasts and phase boundaries; keep trajectory-scale exceptions explicit.

SAY THIS

The numerator measures squared alignment between the true mean gradient and the routed update. The denominator penalizes both the size of the retained signal and the routed noise, scaled by curvature. So a restricted operator can help when it preserves aligned signal while rejecting noisy or irrelevant dimensions. We evaluated this quantity before training across 540 conditions. Its rank correlation is 0.937 with observed norm-matched one-step progress and 0.916 with final accuracy. This is the paper's strongest quantitative result: one operator theory predicts major wins, nulls, and crossovers. It is not a guarantee for every small difference accumulated over a nonlinear trajectory.

LIKELY QUESTION

Does a high U guarantee higher final test accuracy?

ANSWER

No. It is exact for an isotropic quadratic and otherwise a one-step smoothness guarantee. The strong final-accuracy association is empirical validation, not a theorem about all training trajectories.

TRANSITION

The first boundary appears on ordinary image tasks.

STANDARD IMAGE TASKS Neuron-specific feedback dominates standard image tasks

PURPOSE

Establish that neuron identity, rather than exact dendritic address, is the main bottleneck on standard benchmarks.

HOW TO READ IT

Compare adjacent rungs, not absolute axes across datasets. Green denotes shunting on MNIST; blue denotes the additive tree.

CLAIM GUARDRAIL

Do not claim exact dendritic routing is generally needed from these benchmarks; they show the opposite.

SAY THIS

These ladders progressively increase feedback resolution. Moving from one strict layer-wide scalar to one coordinate per neuron improves accuracy by about eight to sixteen percentage points across MNIST and flattened CIFAR-10. Moving from one neuron-specific coordinate to the exact compartment field changes accuracy by less than one point. On CIFAR-10, the exact field is within the predefined one-point equivalence margin of backpropagation. The important conclusion is a boundary, not a universal dendritic benefit: on standard image tasks, preserving which neuron owns a learning signal is much more important than resolving the exact path inside that neuron.

LIKELY QUESTION

Why does the scalar network still learn well?

ANSWER

Every weight retains a distinct eligibility and the forward network retains many hidden units. Scalar feedback restricts task-dependent credit but does not erase representational diversity.

TRANSITION

To make a branch address necessary, the task must demand incompatible updates inside one neuron.

11 Credit conflict creates a demand for branch-specific signals

1:00 · scripted

CONTROLLED TASK 1 - DEFINITION
Credit conflict creates a demand for branch-specific signals

compatible, $\chi = 0$

conflicting, $\chi = 1$

Input
All B branches receive a Fashion-MNIST image and form nonzero eligibility.

forward selector
Context c selects the branch whose image determines the target.

conflict dose χ
Nonselected images vary from class-compatible ($\chi=0$) to opposite-class ($\chi=1$).

$d_{branch_b} = N^{-1} \sum_b \mathbf{1}[c=b] x_{t,b}$

$d_{shared_b} = N^{-1} \sum_b \mathbf{1}[c=b] x_{t,b}$

$\mathbf{1}$ indicator
 $x_{t,b}$ mean update direction for branch b

At zero conflict, one shared signal is sufficient; at high conflict, different branches require opposite updates.

PURPOSE

Define the controlled branch-conflict task before showing its outcome.

HOW TO READ IT

B is the number of branches, c selects the relevant branch, and d_b is the mean update direction assigned to branch b .

CLAIM GUARDRAIL

Call it a controlled existence proof, not a naturalistic benchmark.

SAY THIS

Here every branch is active and therefore has nonzero eligibility, but a context selects which branch determines the label. The conflict parameter χ controls the distractors. At χ equals zero, selected and nonselected streams are class-compatible, so one shared learning signal can work. At χ equals one, the nonselected branches carry the opposite class, so simultaneously active branches require different or opposing updates. The branch-specific rule gates credit by context; the shared rule broadcasts the same value across branches. This is a deliberately constructed existence test of when within-neuron address resolution is required.

LIKELY QUESTION

Was this task designed to favor branch-specific routing?

ANSWER

Yes, deliberately. It is a mechanism-matched necessity test: we vary the precise feature, simultaneous within-neuron credit conflict, that the theory says should create path demand.

TRANSITION

The theory predicts the exact conflict value at which shared credit changes sign.

CONTROLLED TASK 1 - RESULT Shared credit fails at the predicted conflict boundary

PURPOSE

Show that the analytic crossover predicts trained failure and that route assignment is causal.

HOW TO READ IT

Lambda shared is the useful shared-mode coefficient. Its sign change defines chi c; the plotted collapse points track that boundary.

CLAIM GUARDRAIL

The result establishes the need for an address, not a unique material need for a dendritic tree.

SAY THIS

The shared update has an analytic eigenvalue $B - 2\chi(B-1)$. It crosses zero at χ_c equals B over two times $B - 1$. The trained shared rule collapses near this predicted boundary for two, four, and eight branches. At full conflict, branch-specific routing gains thirty-five to fifty-eight percentage points. A cyclic derangement keeps the same rank and sparsity but delivers each channel to the wrong branch, and it fails. Analytic backpropagation, the correct routed field, and a gated-point implementation coincide because they are equivalent calculations of the same routing matrix.

LIKELY QUESTION

Why does the critical conflict depend on B?

ANSWER

One selected stream contributes useful signal while $B - 1$ distractors contribute conflicting signal. Increasing B changes that balance and shifts the zero crossing.

TRANSITION

A second task asks whether a small hierarchy of addresses can be efficient.

13 Nested tasks ask whether a few subtree addresses are efficient

0:50 · scripted

CONTROLLED TASK 2 - DEFINITION

Nested tasks ask whether a few subtree addresses are efficient

$$\delta^V = A_K c, \text{ rank}(A_K) = K$$

B Feedback bandwidth within one neuron

matched controls
Rank, sparsity, parameter count, and forward resources are held fixed; only route assignment, basis, or topology changes.

Intermediate K tests whether tree-structured feedback is a useful low-dimensional basis for task credit.

PURPOSE

Define the hierarchy task and make clear that K is feedback bandwidth.

HOW TO READ IT

The four route diagrams increase within-neuron bandwidth K from one to full rank eight.

CLAIM GUARDRAIL

Do not let the audience interpret K as number of dendritic levels.

SAY THIS

The next task has eight input streams organized by a nested context hierarchy. We expose only K independent feedback channels inside each neuron: one shared channel, two coarse subtrees, four intermediate subtrees, or eight leaf-specific channels. A K therefore has rank K. We compare true ancestry routes with derangements and matched non-anatomical low-rank bases while holding forward resources, rank, sparsity, and parameter count fixed. K is feedback bandwidth, not physical dendritic depth. The hypothesis is that a tree becomes an efficient basis only when the task's credit covariance has a compatible nested structure.

LIKELY QUESTION

Is increasing K the same as adding dendritic depth?

ANSWER

No. K counts independent returned coordinates. Physical depth changes the forward serial computation and is a separate experiment kept in backup.

TRANSITION

The result separates address ownership from the smaller contribution of this particular topology.

CONTROLLED TASK 2 - RESULT

Subtree addresses help—but fine topology adds only a narrow gain

PURPOSE

Separate the large value of correct address assignment from the small topology-specific effect.

HOW TO READ IT

Compare correct ancestry first with derangement, then with the best rank- and sparsity-matched alternative. Those contrasts answer different questions.

CLAIM GUARDRAIL

Always pair the large assignment effect with the modest topology-specific effect.

SAY THIS

At intermediate bandwidth K equals four, assigning the channels to the correct subtrees beats a cyclic derangement by sixty-one percentage points. That is the large address-assignment effect. But against the strongest matched non-anatomical low-rank basis, the ancestry advantage is only 1.27 points. Ancestry loses at K equals one and two, wins at K equals four, and ties at full rank. Rewiring removes the intermediate gain. Dendritic, grouped-point, and gated-point implementations coincide when they receive the same routed field. So the robust conclusion is that correct addresses matter; the extra value of nested anatomy is narrow and task-matched.

LIKELY QUESTION

Does the sixty-one-point effect prove that dendritic topology is superior?

ANSWER

No. It proves that correct channel-to-subtree assignment matters. The topology-specific comparison is the much smaller 1.27-point advantage over the best matched alternative at K equals four.

TRANSITION

If biological trees are candidate route dictionaries, how much field can real arbors represent per connection?

BIOLOGICAL CAPACITY

Real arbors provide sparse candidate routes, mostly through coarse geometry

PURPOSE

Present anatomy as route capacity, not evidence of biological use.

HOW TO READ IT

$P A$ projects a field q into the span of the route matrix A . Capture ranges from zero to one.

CLAIM GUARDRAIL

Pair 14.2-fold with the density-matched approximately 2.7-fold control and call the second-mouse result descriptive.

SAY THIS

We map excitatory and inhibitory contacts onto reconstructed MICrONS arbors and use branch points to define nested route supports. Capture is the fraction of a target field's energy that lies in the route span. These sparse dictionaries retain about eighty-five percent of dense capture using about seven percent of the dense route-matrix connections. That is a 14.2-fold dense-normalized ratio, but the anatomy-specific advantage over a density-matched shuffled dictionary is closer to 2.7-fold. The ordering replicates in held-out cells and a small second-mouse cohort. Most of the capacity is explained by coarse branch geometry.

LIKELY QUESTION

Does high capture show that the animal uses these routes for learning?

ANSWER

No. It shows representational capacity of modeled route dictionaries. It does not measure endogenous task gradients or demonstrate plasticity through those routes.

TRANSITION

Anatomy supplies addresses; conductance can in principle regulate their gain.

ROUTE GAIN
Focal shunting changes descendant credit only in permissive regimes

$\partial \log \alpha^{(m)}_k / \partial G_k = -R^{(m)}_k \cdot 1[k \in (a)]$

A shunt directly attenuates only routes descending through compartment k, the effect scales with total input resistance.

matched additive current
somatic voltage restored
local dendritic voltage is not restored

focal shunting conductance
dependent route
only the shunt changes G

standard passive calibration
At $R_{in} = 15,000 \Omega \text{ cm}^2$, the shunt minus current localization contrast is effectively zero.

high-conductance regime
Descendant localized changes emerge and survive active-channel extensions.

Shunting is a state-dependent route-gain mechanism, not a generic learning advantage.

SAY THIS

We compare a focal inhibitory conductance with an additive current chosen to match the baseline first-order focal current, then restore somatic voltage. The local dendritic voltage is intentionally not matched, because the question is whether conductance changes sensitivity beyond current injection. In the directed tree, the log gain of a descendant route changes in proportion to minus the local input resistance when the shunt lies on that route. At the standard passive calibration the localization contrast is essentially zero. In high-conductance, electrotonically permissive regimes, descendant-localized changes emerge and survive active-channel extensions. Shunting is therefore a conditional gain mechanism, not a generic learning improvement.

PURPOSE

Explain the mechanistic contrast and foreground the standard-calibration null.

HOW TO READ IT

The indicator is one only for descendants of compartment k, and the effect scales with R total k.

CLAIM GUARDRAIL

Do not imply that shunting improves training generically or that local voltage was matched.

LIKELY QUESTION

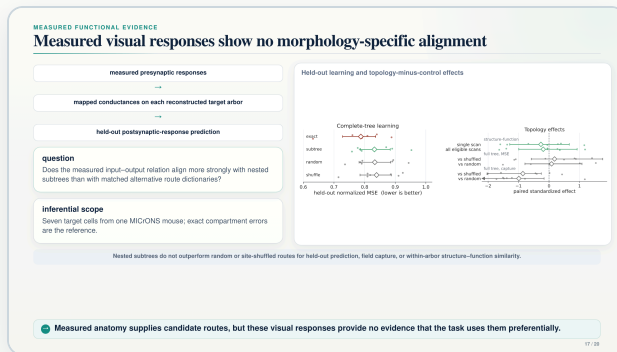

Is the main shunting result positive or null?

ANSWER

At the standard passive calibration it is null. The positive localization appears in a defined permissive high-conductance regime, which is why the claim is conditional.

TRANSITION

Capacity and conditional gain still do not show that measured cortical function uses these routes.

SAY THIS

For seven reconstructed target cells from one MICrONS mouse, we map measured presynaptic visual responses through the conductance model and test held-out postsynaptic-response prediction. Nested subtrees do not outperform random or site-shuffled route dictionaries for held-out learning, field capture, or within-arbor structure-function similarity. The effects are centered near zero. This is an important boundary: measured anatomy offers possible addresses, but these visual-response data do not reveal preferential alignment between those addresses and the functional relation being modeled. The cohort is small and does not measure plasticity, so the result is a scoped null rather than a general rejection of dendritic learning.

PURPOSE

State the biological null as a headline result and define its inferential scope.

HOW TO READ IT

The pipeline moves from measured presynaptic responses to mapped conductances and then held-out postsynaptic prediction; the contrast plot compares topology with matched controls.

CLAIM GUARDRAIL

Say seven cells and one mouse aloud; never generalize the null beyond this cohort and assay.

LIKELY QUESTION

Does this rule out morphology-specific credit assignment in cortex?

ANSWER

No. It rules out a detectable advantage in this seven-cell, one-mouse visual-response analysis. Other tasks, states, cell types, or direct plasticity measurements could differ.

TRANSITION

We therefore ask the narrower causal question: would the same routes help if the task field were aligned to them?

CONTROLLED ALIGNMENT RESCUE

The same anatomical routes capture task credit aligned to their span

$$\varphi(a) = \sqrt{a} u_{\parallel} + \sqrt{1-a} u_{\perp}, \quad a \in [0,1]$$
$$u_{\parallel} \in \text{col}(A), \quad u_{\perp} \perp \text{col}(A), \quad \|u_{\parallel}\| = \|u_{\perp}\| = 1$$

Imposed alignment

$a = 0$
 $a = 0.4$
 $a = 1$

controlled quantity

Anatomy, field energy, curvature, and route count are fixed; only alignment with the subtree span changes.

$n = 5$ reconstructed cells

Controls test whether the gain is specific to the true subtree span. The manipulation proves conditional representational sufficiency—not learned tuning or endogenous biological use.

Alignment is sufficient for representational capture in the model; endogenous morphology-specific alignment remains unestablished.

PURPOSE

Show controlled sufficiency of alignment without implying endogenous biological use.

HOW TO READ IT

$u_{\parallel}$ parallel lies in the column space of A and $u_{\perp}$ perpendicular is orthogonal to it. The square roots keep total field energy fixed.

CLAIM GUARDRAIL

Use the phrase conditional representational sufficiency.

SAY THIS

We construct a fixed-energy field φ of a by rotating between a unit vector inside the anatomical route span and an orthogonal unit vector. Anatomy, field energy, curvature, and route count remain fixed; only alignment a changes. By construction, anatomical capture increases linearly with a , and the true subtree routes outperform matched controls as the field enters their span. This rescue shows that the anatomical dictionary is sufficient to represent a task field when the geometry is matched. It does not show that alignment was learned, that these are endogenous cortical error signals, or that the manipulation improves a trained network.

LIKELY QUESTION

Is this a trained-learning experiment?

ANSWER

No. It is a controlled representational analysis. Its purpose is to isolate alignment as the missing variable after the measured-response null.

TRANSITION

The standard tasks, controlled positives, and biological nulls now occupy one common phase plane.

SYNTHESIS One alignment–bandwidth plane organizes the wins and nulls

PURPOSE

Give the audience one unifying map rather than a list of disconnected results.

HOW TO READ IT

Move right for stronger task-route alignment and up for more independent feedback coordinates relative to effective credit rank.

CLAIM GUARDRAIL

Do not treat approximate point placement as a universal calibrated phase diagram.

SAY THIS

The horizontal axis is task-route alignment: how much demanded credit lies in the available route span. The vertical axis is feedback bandwidth relative to the effective dimensionality of the task-credit field. Low bandwidth creates a coordinate or address bottleneck. At aligned intermediate bandwidth, restricted routes can preserve useful signal while rejecting irrelevant dimensions. At full rank, route capacity saturates; at weak alignment, extra structure cannot help. Each experiment estimates its coordinates separately. The background regimes and the bandwidth-equals-effective-rank boundary are theoretical, not fitted to the outcome points.

LIKELY QUESTION

Was the phase boundary fitted to these experiments?

ANSWER

No. The regime tint and K over effective-rank equals one line come from the operator theory. Experimental coordinates are estimated independently within each assay.

TRANSITION

This leaves four conclusions, ordered by what the evidence establishes most strongly.

TAKE-HOME
Coordinate → address → gain, all conditional on task–route alignment

coordinate → address → gain
which neuron? which address? how strongly? enabled by alignment × bandwidth

1 - neuron-specific coordinates come first
Across MNIST and Italianet CIFAR-10, preserving distinct feedback across neurons closes most of the scalar-to-exact gap.

2 - addresses matter when local updates conflict
Branch-specific signals become necessary when simultaneously active addresses require different or opposite changes.

3 - topology helps only in a matched regime
Nested routes add a modest advantage at intermediate aligned bandwidth; reconstructed errors supply sparser candidate routes.

4 - conductance regulates gain conditionally
Focal shunting localizes modulated credit only in permissive states, and endogenous morphology-specific use remains unestablished.

Dendrites are a conditional substrate for routing local credit—not a general replacement for backpropagation.

The central contribution is a predictive boundary map: when restricted dendritic routes help, when they do not, and why.

PURPOSE

End with four defensible statements and one memorable novelty claim.

HOW TO READ IT

The final flow is coordinate, address, and gain, gated jointly by alignment and bandwidth.

CLAIM GUARDRAIL

Finish on the conditional theory; do not inflate anatomy or shunting into universal benefits.

SAY THIS

The first requirement is neuron-specific coordinate: it closes most of the scalar-to-exact gap on standard tasks. Within-neuron addresses become necessary when simultaneously active branches require conflicting updates. Nested topology adds a modest advantage only at matched intermediate bandwidth, while real arbors provide sparse candidate routes. Conductance can regulate route gain in permissive states, but measured endogenous use remains unestablished. The central contribution is therefore not that dendrites always improve learning. It is a predictive boundary map of when restricted dendritic routes should help, when they should not, and why.

LIKELY QUESTION

What is the one-sentence novelty?

ANSWER

A stochastic credit-operator theory quantitatively predicts when restricted dendritic routes preserve useful learning signal, and controlled experiments map both its positive regimes and its null boundaries.
